BIOLEACHING OF METALS FROM POLISH BLACK SHALE IN NEUTRAL MEDIUM

The black shale present in Polish ores (Lubin region) differs from others in mineralogical and chemical properties and in susceptibility to enrichment. The ores are characterized by high content of copper and other metals like silver. Some metals in the shale ore are present as bituminous organo-metallic compounds such as porphyrins. The presence of these compounds reduces metals recovery by classical acid bioleaching methods. This study has been undertaken in order to determine possibilities of metals bioleaching from the sandwich compounds occurred in black shale. The bioleaching process was carried out in neutral medium using *Bacillus cereus* and *Bacillus amyloliquefaciens* strains. The progress of this process was followed by analysis of copper, zinc and nickel bioleaching kinetics. The bioleaching experiments with copper suggest different organic forms of this metal in the shale ore. Some of them are highly susceptible to bioleaching by heterotrophic bacteria. Organic compounds of the nickel appeared to be more resistant to bioleaching than copper compounds. Bioleaching of zinc was negligible. Also, the bioleaching process was carried out on a batch scale using “Biomel” reactor.

Key words: bioleaching, black shale ore, Bacillus cereus, Bacillus amyloliquefaciens

INTRODUCTION

The Lubin deposits of a cupriferous ore consist of three lithological forms: carbonate, sandstone and shale. Shale ores containing a bituminous component are called the black shale. Main components of the black shale are loams, carbonate minerals, organic compounds and detrital minerals [Kucha et al., 1996; Łuszczkiewicz, 2000]. In the black shale some organic matter occurs in a shape of lammas, small inclusions, loamy interlayers and organic remnants. The contents of the
organic matter fluctuate from 1% to 30% with 6% on average; however, the contents of bitumen range from 1% to 11% [Speczik et al., 1996]. The black shale ores differ from others in mineralogical and chemical properties and in a susceptibility of recovery. They are characterized by high content of copper (5.5 %) and other metals like silver (0.01 %). In the bituminous shale ore the content of metals is from 3 to 10 times greater than that in carbonate and sandstone forms [Luszczkiewicz, 2000]. Therefore this ore can be treated as a natural polymetallic concentrate.

Some metals in the shale ore are present as bituminous organo-metalliic compounds as porphyrinus. The presence of these compounds, reduces the metals recovery by using classical methods of ore enrichment. [Luszczkiewicz, 2000]

This study has been undertaken to determine the possibilities of bioleaching of metals from sandwich compounds occurring in Lubin (Poland) black shale. The bioleaching process was carried out in neutral medium with Bacillus bacteria strains. The progress of this process was followed by analysis of bioleaching kinetics of copper, zinc and nickel recovery.

**MATERIALS AND METHODS**

**MATERIAL**

Cupriferous black shale ore was obtained from the Lubin region in Poland. The shale was initially subjected to acid bioleaching, then after extensive washing with distilled water the second bioleaching step was performed under neutral pH condition. Material prepared by this means contained 1.58% Cu, 0.67% Pb, 0.27% Zn and 0.006% Ni.

**ISOLATION OF MICROORGANISMS**

The bioleaching process was carried out using autochthonous bacteria. Bacillus bacteria strains were isolated by our team from the investigated shale samples. Microorganisms were washed out from black shale with physiological solution. The suspended matter was diluted by Lister method from $10^{-1}$ to $10^{-6}$. About 0.1 cm$^3$ of diluted fluid ($10^{-5}$ and $10^{-6}$) was taken from test-tubes and placed on nutrient agar. After 24 hour of aerobic incubation at 30°C, the grown bacterial culture was transferred into flasks with enriched broth.

In order to select Bacillus bacterial strains with spores, flasks with bacterial culture were pasteurized [Chmiel, 1998; Kunicki-Goldfinger, 1998]. In the next step of experiment we screened them on the solid medium and transferred onto a thiolignin medium, specific for Bacillus, followed by 24 hour aerobic incubation at 30°C. As a result two aerobic, Bacillus strains (designated as B$_1$ and B$_2$) were obtained and identified. The first step in identification process involved staining using Gramm method [Singleton, 2000]. In all cases Gram (+) batch were observed and then tested on a microanalizer API. The isolated B$_1$ and B$_2$ strains were identified as B. cereus and designed as B.c.-04, and B. amyloliquefaciens designed as B.a.-04, respectively.
This identification was confirmed using Moseley medium. In the case of the B1 strain the plates were colored red indicating the Bacillus cereus strain. Next the cultures were grown on the enriched broth.

BACTERIAL STRAINS CHARACTERISTICS

Bacillus cereus is an aerobic or relatively aerobic, Gram(+) bacterium that can produce resting spores. This bacillary bacterium (3-5 µm in length and 1.0 -1.2 µm in wide) has a flagellum and tends to form chain-like colonies. It grows from 5º to 50ºC of pH 5.5-8.5 with a water activity of aw = 0.95. Our B. cereus strain hydrolyzes casein, starch, gelatin and decomposes glucose and tyrosine. Extracellular products of the bacterium contain hemolysins, lytic (included proteolytic) enzymes, and phospholipase. Some strains of this bacterium under certain conditions produce red or fluorescent yellow-green pigment. [Bergley, 1986]. B. cereus strains are frequently found in soil, water and sewage. This bacterium can contaminate food-products and during their growth in food or intestines produce poisonous endotoxins [Prescott et al., 1999; Libudzisz et al., 2000].

Bacillus amyloliqueficiens strain was isolated and identified as a different Bacillus subtilis strain by Welker and Campbell in 1967. They found the difference between mole% G+C in DNA of B. amyloliqueficiens (43.5-44.9) and DNA of B.subtilis (42.0-43.0). The DNA hybridization of these species shows only 15% of homology explaining some different properties of the species. They contain an inducible amylase gene that can produce great amounts of active α-amylase enzyme. B. amyloliqueficiens cells are 2-3 µm in length and 0.7-0.8 µm wide. This strain is an aerobic or relatively aerobic, Gram(+) bacteria strain, with resting spores. The temperature of the bacterium growth is in the range 5º-50ºC, pH = 6-8 [Bergley, 1986].

BIOLEACHING EXPERIMENTS

Bioleaching of metals from black shade was carried out in Erlenmayer flasks on a small laboratory scale. The leaching medium contained 0.75% KNO3, 0.1% K2HPO4 and 0.05% MgSO4 • H2O. The active bacteria strains found in the culture were B.c.-04 and B.a.-04, in ratio 1:1 and the solid phase to liquid phase ratio was 5:1. Experiments were performed during 28 days in three batches at 10º, 20º and 40ºC. The pH value was brought close to pH 7. Three control systems, with thymol as a bacteriostatic substance, were simultaneously prepared.

The progress of the extraction process was monitored by measurements of the concentration of following ions: Cu²⁺ every three-four days, Ni²⁺ in the third and the last day and Zn²⁺ at the end of the experiment. All these measurements were performed using ASA method. An acidity of systems were checked twice a day and adjusted to pH 7 with 10% NaOH.

The bioleaching process was carried out over 24 days in the „Biomel” batch reactor, at 25ºC with a continuous aeration and mixing (300 r.p.m.). Samples of 400
g black shale ore were placed into 3400 cm$^3$ leaching medium containing Mg$^{2+}$, SO$_4^{2-}$, K$^+$, HPO$_4^{2-}$, NO$_3^-$ and 600 cm$^3$ inoculated broth. The active bacteria strains in the culture were *B. cereus* - B.c.-04 and *B. amyloliquefaciens* - B.a.-04, mixed in a ratio of 1:1. The pH value was brought close to pH 7.0 with 10% NaOH. Simultaneously, we prepared control reaction mixtures that contained 400 g black shale and 4000 cm$^3$ leaching medium with 20 g thymol as a bacteriostatic agent. The concentration of ions was determined every 3-4 days as follows: Cu$^{2+}$ by ASA method, concentration Fe$^{2+}$ and Fe$^{3+}$ by a compleximetric titration, and Ni$^{2+}$ by ASA method when process was finished.

**RESULTS AND DISCUSSION**

We studied bioleaching of copper, nickel and zinc ions from the black shale during 28 days of process duration. The extension of the leaching process in the studied and control systems at three temperatures is shown in Figure 1, 2 and 3.

![Graph showing Cu concentration over time](image)

**Fig. 1.** The effect of temperature on the copper bioleaching during 28 days of process (10ºC, 20ºC and 40ºC)

In the first three days of leaching, the concentration of copper increased quickly up to 40 mg/dm$^3$ at the three temperatures. For the next seven days, bioleaching process was not observed (Figure 1) at 10ºC. After 20 days the process started again and the concentration of Cu$^{2+}$ ions increased up to 55 mg/dm$^3$ (1.7% copper contained in the studying shale). At 20ºC, the leaching of copper stopped after seven days (leaching concentration 59 mg/dm$^3$). Some leaching was observed again after 20$^{th}$ day of the
process duration (Figure 1). In the last day of studies the concentration of Cu^{2+} ions reached 75 mg/dm^3 (2.4%). The maximum concentration of copper (90 mg/dm^3) was found in the 28th day of the leaching, at 40°C. We were able to extract 2,8% copper contained in the black shale (Figure 1). In all control systems, no leaching of copper was observed that indicating only biological leaching (Figure 1) in the studied samples.

The concentrations of nickel ions were measured only in the third and the last day of the process duration. Figure 2 shows the values obtained for nickel leaching. As can be seen, bioleaching process was not observed in the first three days (at the same time the quantity of leached Cu^{2+} ions was greatest). In the 28th day bioleaching of nickel was highest at 40°C and reached up to level 1.2 mg/dm^3 (10% nickel contained in the studying shale). The levels of leached nickel at 10° and 20°C were 6% and 9%, respectively (Figure 2).

![Figure 2: The effect of temperature on Ni bioleaching during 28 days of process](image)

The concentrations of zinc ions were determined only in the 28th day of process duration (Figure 3). Bioleaching was highest at 40°C but only 0,007% zinc was released.

In order to obtain more information, the bioleaching experiment was carried out on a bench scale. The conditions for bioleaching process were similar with the condition used in laboratory experiments (neutral medium, heterotrophic bacteria *B. cereus* - B.c.-04 and *B. amyloliquefaciens* - B.a.-04). The results are shown in Figure 4.
Fig. 3. The bioleaching of Zn during 28 days of process at 10°, 20° and 40° C

Fig. 4. The bioleaching of copper during 24 days of process
The process of copper leaching started in the 3rd day and ran most intensely between the 3rd and 7th day. As shown in Figure 4 the slope of the curve decreases after 7 days indicating that the rate of extraction process decrease after that time. However, there was a significant overall rate of copper production between the 7th and 21st day. In the last three days the reaction was very slow. The first three days represent an adaptation period for microflora. The microflora adapted well to gentle mixing, however it was shocked by intensive mixing in a bioreactor. The intensive mixing was necessary for keeping an uniform ore suspension.

The bioleaching and leaching data are presented in Table 1.

CONCLUSIONS

The results of our experiments have confirmed predications that copper, nickel and zinc contained in Polish black shale appear in organo-mettalic compounds, because they can be extracted by bioleaching with B. cereus and B. amyloliquefaciens strains. The bioleaching experiments with copper (Figure 1) suggest different organic forms of this metal in the shale ore. Some of them are highly susceptible to bioleaching by heterotrophic bacteria during the first three days. The others extracted only after 14 days of the process duration at 40°C (Figure 1). We have also found that up to 10% of nickel still remaining in the black shale after acid bioleaching is an organic nickel. The organic compounds of the nickel appeared to be more resistant to bioleaching than the quickly dissolving copper compounds (Figure 2).
